The conversion time is 2 times the normal-time conversion time when:
- The first AD conversion is performed in the 10-bit AD conversion mode after a system reset.
- The first AD conversion is performed after the AD conversion mode is switched from 8-bit to 10-bit conversion mode.

The oscillation stabilization time refers to the time interval that is required for the oscillation to get stabilized after the instruction for starting the subclock oscillation circuit is executed and to the time interval that is required for the oscillation to get stabilized after the HOLD mode is reset (see Figure 3).

Note: The components that are involved in oscillation should be placed as close to the IC and to one another as possible because they are vulnerable to the influences of the circuit pattern.

Figure 6 Pulse Input Timing Signal Waveform

Figure 7 Waveform observed when only POR is used (LVD not used)
(RESET pin: Pull-up resistor R$_{RES}$ only)

- The POR function generates a reset only when power is turned on starting at the V$_{SS}$ level.
- No stable reset will be generated if power is turned on again when the power level does not go down to the V$_{SS}$ level as shown in (a). If such a case is anticipated, use the LVD function together with the POR function or implement an external reset circuit.
- A reset is generated only when the power level goes down to the V$_{SS}$ level as shown in (b) and power is turned on again after this condition continues for 100μs or longer.
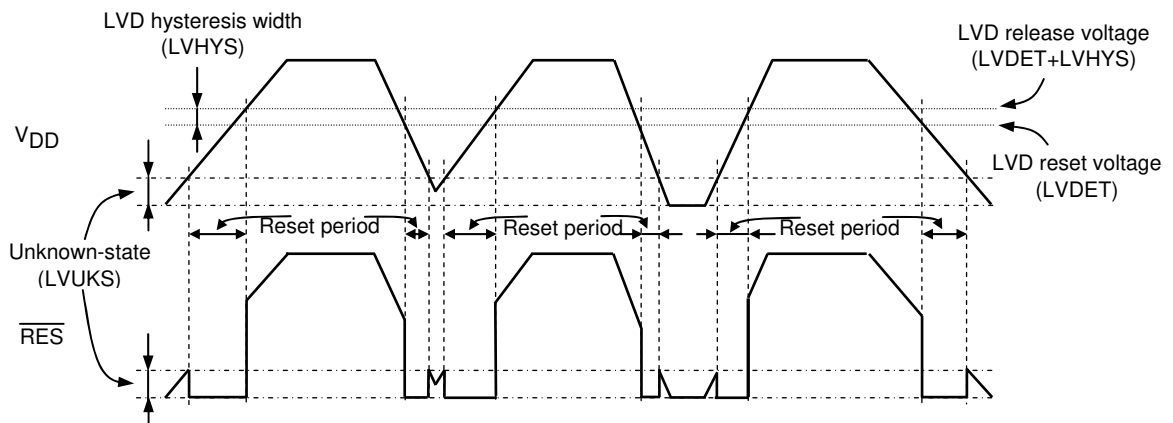

Figure 8 Waveform observed when both POR and LVD functions are used
(RESET pin: Pull-up resistor R$_{RES}$ only)

- Resets are generated both when power is turned on and when the power level lowers.
- A hysteresis width (LVHYS) is provided to prevent the repetitions of reset release and entry cycles near the detection level.
