## 10-Bit, 20 MSPS A/D Converter

### Features

- Resolution 10-Bit  $\pm 0.5$  LSB (DNL)
- Maximum Sampling Frequency 20 MSPS
- Low Power Consumption 140mW (Reference Current Excluded)
- Standby Mode Power 5mW
- No Sample and Hold Required
- TTL/CMOS Compatible I/O
- Three-State Outputs
- Single +5V Analog Power Supply
- Single +3.3V or +5V Digital Power Supply
- Evaluation Board Available: HI5710EVAL

### Applications

- Video Digitizing - Multimedia
- Data Communications
- Image Scanners
- Medical Imaging
- Video Recording Equipment
- Camcorders
- QAM Demodulation

### Description

The HI5710 is a low power, 10-bit, CMOS analog-to-digital converter. The use of a 2-step architecture realizes low power consumption, 140mW, and a maximum conversion speed of 20MHz with only a 3 clock cycle data latency. The HI5710 can be powered down, disabling the chip and the digital outputs, reducing power to less than 5mW. A built-in, user controlled, calibration circuit is used to provide low linearity error, 1 LSB. The low power, high speed and small package outline make the HI5710 an ideal choice for CCD, battery, and high channel count applications.

The HI5710 does not require an external sample and hold but requires an external reference and includes force and sense reference pins for increased accuracy. The digital outputs can be inverted, with the MSB controlled separately, allowing for various digital output formats. The HI5710 includes a test mode where the digital outputs can be set to a fixed state to ease in-circuit testing.

2. N: Non-Inverted Output.
3. I: Inverted Output.

**Detailed Description**

The HI5710 is a two step A/D converter featuring a 5-bit upper comparator group and a 5-bit lower comparator group. An internal calibration mode is used to improve linearity which is user controlled.

The reference voltage must be supplied externally, with  $V_{RB}$  and  $V_{RT}$  typically set to 2.0V and 4.0V respectively.

Both chip enable and output enable pins are provided for flexibility and to reduce power consumption. The digital outputs can be inverted by inputs LINV and MINV, where LINV controls outputs D0 through D8 and MINV controls output D9 (MSB). This allows for outputs of various digital formats, such as straight binary, inverted binary, offset two's complement or inverted offset two's complement.

**Analog Input**

The analog input typically requires a  $2V_{p,p}$  full scale input signal. The full scale input can range from 1.8V to 2.8V depending on the reference voltages.

The input capacitance is small when compared with other flash type A/D converters. However, it is necessary to drive the input with an amplifier with sufficient bandwidth and drive capability. Op amps such as the HA5020 should make an excellent input amplifier depending on the applications requirements. In order to prevent parasitic oscillation, it may be necessary to insert a resistor between the output of the amplifier and the A/D input. Be sure to consider the amplifiers settling time in CCD applications or where step inputs are expected.

**Reference Input**

The input range of the A/D is set by the voltage difference of  $V_{RT}$  and  $V_{RB}$ . The HI5710 is designed to use an external reference from 2.0V to 4.0V on  $V_{RB}$  and  $V_{RT}$ , respectively. The analog input range of the A/D will now be from 2.0V to 4.0V. The  $V_{RB}$  range is 1.8V to 2.8V, the  $V_{RT}$  range is 3.6V to 4.6V, and ( $V_{RT} - V_{RB}$ ) range is 1.8V to 2.8V.

$V_{RT}$  and  $V_{RB}$  must be decoupled to analog ground to minimize noise on the reference. A 0.1µF capacitor is usually adequate.

**Clock Input**

The HI5710 samples the input signal on the rising edge of the clock with the digital data latched at the output after 3 clock cycles. The HI5710 is designed to use a 50% duty cycle square wave, but a 10% variation should not affect performance.

The clock input can be driven from +3.3V or +5V TTL or CMOS logic. Be sure not to use +5V logic if the HI5710 digital supply is +3.3V, unless you are sure the input will not exceed the supply voltage. When using a +3.3V digital supply, HC or AC CMOS logic will work well.

**Digital Inputs**

The digital inputs can be driven from +3.3V or +5V TTL or CMOS logic, except for the  $\overline{OE}$  input. The  $\overline{OE}$  input should be driven by CMOS logic when using a +5V digital supply though TTL logic may work if not heavily loaded. Be sure not to use 5V logic if the HI5710 digital supply is +3.3V, unless you are sure the input will not exceed the supply voltage. When using a +3.3V digital supply, HC or AC CMOS logic will work well.

**Digital Outputs**

The digital outputs are CMOS outputs. The LINV input will invert outputs D0 through D8 and MINV will invert output D9 (MSB). This allows the user to set the output for a number of different digital formats. The outputs can also be three-stated by pulling the  $\overline{OE}$  input high.

The digital supply can run from +3.3V to +5V. The digital outputs will generate less radiated noise using +3.3V, but the outputs will have less drive capability. The digital outputs will only swing to  $DV_{DD}$ , therefore exercise care if interfacing to +5V logic when using a +3.3V supply.

The outputs can also be set to a fixed, defined state, see Output Data Format table. By setting the TESTMODE pin low, the outputs go to a defined digital pattern. This pattern is varied by the MINV and LINV inputs. This feature can be used for in-circuit testing of the digital bus.

**Calibration Function**

The HI5710 has a built-in calibration circuit to minimize linearity error. The RESET and CAL inputs should be timed as

shown in Figure 4. A setup time of 10ns or longer is required for both the RESET and CAL inputs and they must stay low for at least one clock period.

A negative pulse on the RESET input should occur before the CAL input sees a falling edge. This sets up the initial calibration value. The calibration starts on the rising edge of the clock after the falling edge of the CAL pulse and requires 300 pulses to complete the calibration. The RESET input serves to minimize the calibration time, but it is not mandatory that it be used. The RESET input must remain at a high state when not in use. The calibration, when executed without the RESET pulse, requires 600 calibration pulses.

One calibration cycle is completed in 11 clock cycles. Seven clock cycles after the calibration pulse, the calibration circuit takes exclusive possession of the lower comparators, D0 through D4, for four clock cycles. During this time, the outputs are latched with the previous data (cycle seven data).

The upper 5 bits, D5 through D9, will operate as usual during the calibration if the SEL input is held high, making the HI5710 a 5 bit A/D converter during the last four clock cycles of the calibration. If the SEL input is low, the upper 5 bits are latched with the previous data (cycle seven data) during the last four cycles of the calibration as are the lower 5 bits.

The calibration must be done when the part is first powered up, when the supplies vary more than 100mV or when  $(V_{RT} - V_{RB})$  changes more than 200mV. When first powered up, a minimum of 300 calibration pulses are required after the reset pulse is given, then a minimum of 600 calibration pulses are needed. Figure 4 shows several possible calibration timing schemes. It is not necessary to calibrate as often as these figures show, these are only design ideas. The HI5710 application note AN9511 shows a simple circuit for controlling the calibration function.

**Power, Grounding, and Decoupling**

To reduce noise effects, separate the analog and digital grounds. Bypass both the digital and analog  $V_{DD}$  pins to their respective grounds with a ceramic 0.1µF capacitor close to the pin. A larger capacitor (1µF to 10µF) should be placed somewhere on the PC board for low frequency decoupling of both analog and digital supplies.

The analog supply should be present before the digital supply to reduce the risk of latch-up. The digital supply can run from +3.3V to +5V. +3.3V generates less radiated noise at the digital outputs, but they have less drive capability. The specifications do not change with digital supply levels. Remember, the digital outs will only swing to  $DV_{DD}$ .

### Timing Definitions

**Aperture Delay** - Aperture delay is the time delay between the external sample command (the falling edge of the clock) and the time at which the signal is actually sampled. This delay is due to internal clock path propagation delays.

**Aperture Jitter** - This is the RMS variation in the aperture delay due to variation of internal clock path delays.

**Data Latency** - After the analog sample is taken, the data on the bus is output at 3rd cycle of the clock. This is due to the pipeline nature of the converter where the data has to ripple through the stages. This delay is specified as the data latency. After the data latency time, the data representing each succeeding sample is output at the following clock pulse. The digital data lags the analog input by 3 cycles.

**Power-up initialization** - This time is defined as the maximum number of clock cycles that are required to initialize the converter at power-up. The requirement arises from the need to initialize some dynamic circuits within the converter.

### Static Performance Definitions

Offset, full-scale, and gain all use a measured value of the external voltage reference to determine the ideal plus and minus full-scale values. The results are all displayed in LSBs.

**Offset Error ( $V_{OS}$ )** - The first code transition should occur at a level 1/2 LSB above the negative full-scale. Offset is defined as the deviation of the actual code transition from this point. Note that this is adjustable to zero.

**Full-Scale Error (FSE)** - The last code transition should occur for an analog input that is 1 and 1/2 LSBs below positive full-scale. Full-scale error is defined as the deviation of the actual code transition from this point.

**Differential Linearity Error (DNL)** - DNL is the worst case deviation of a code width from the ideal value of 1 LSB. The converter is guaranteed for no missing codes over all temperature ranges.

**Integral Linearity Error (INL)** - INL is the worst case deviation of a code center from a best fit straight line calculated from the measured data.

**Power Supply Rejection (PSRR)** - Each of the power supplies are moved plus and minus 5% and the shift in the offset and gain error is noted. The number reported is the percent change in these parameters versus full-scale divided by the percent change in the supply.

### Dynamic Performance Definitions

Fast Fourier Transform (FFT) techniques are used to evaluate the dynamic performance of the HI5710. A low distortion sine wave is applied to the input, it is sampled, and the output is stored in RAM. The data is then transformed into the frequency domain with a 2048 point FFT and analyzed to evaluate the dynamic performance of the A/D. The sine wave input to the part is -0.5dB down from full-scale for all these tests. The distortion numbers are quoted in dBc (decibels with respect to carrier) and **DO NOT** include any correction factors for normalizing to full scale.

**Signal-to-Noise Ratio (SNR)** - SNR is the measured rms signal to rms noise at a specified input and sampling frequency. The noise is the rms sum of all of the spectral components except the fundamental and the first five harmonics.

**Signal-to-Noise + Distortion Ratio (SINAD)** - SINAD is the measured rms signal to rms sum of all other spectral components below the Nyquist frequency excluding DC.

**Effective Number Of Bits (ENOB)** - The effective number of bits (ENOB) is derived from the SINAD data. ENOB is calculated from:

$$\text{ENOB} = (\text{SINAD} - 1.76 + V_{\text{CORR}}) / 6.02$$

where:  $V_{\text{CORR}} = 0.5\text{dB}$

**2nd and 3rd Harmonic Distortion** - This is the ratio of the rms value of the 2nd and 3rd harmonic component respectively to the rms value of the measured input signal.

**Transient Response** - Transient response is measured by inputting a step to the input to the part and measuring the number of cycles it takes for the output code to settle within a defined accuracy.

**Overvoltage Recovery** - Overvoltage Recovery is measured by inputting a step, which overdrives the input by 200mV, and measuring the number of cycles it takes for the output code to settle within a defined accuracy.

**Full Power Input Bandwidth** - Full power bandwidth is the frequency at which the amplitude of the digitally reconstructed output has decreased 3dB below the amplitude of the input sine wave. The input sine wave has a peak-to-peak amplitude equal to the reference voltage. The bandwidth given is measured at the specified sampling frequency.
