## description

These octal bus transceivers are designed for asynchronous, bidirectional communication between data buses. The devices transmit data from the A Bus to the B Bus or from the B Bus to the A Bus, depending on the level at the direction control input, DIR. The enable input  $\bar{G}$ , can be used to disable the device so that the buses are isolated. These devices will also generate parity outputs, APO and BPO, which reflect the number of high levels at the A Bus and B Bus, respectively, taking into account the parity inputs API and BPI.

The bidirectional I/O ports feature active circuitry on the input stage that, when the output shared by that pin is disabled, will maintain the input in the last state taken by the output. This state will be maintained until changed by the activity on the bus. The advantage of this arrangement is that when all outputs on the bus are disabled, the inputs will be prevented from floating, resulting in minimum power dissipation and minimum susceptibility to noise. This eliminates any need for external pull-up or pull-down resistors. The parity inputs API and BPI have similar circuitry. For further information, see the Typical Application Data.

The SN54HC664 and SN54HC665 are characterized for operation over the full military temperature range of  $-55^{\circ}\text{C}$  to  $125^{\circ}\text{C}$ . The SN74HC664 and SN74HC665 are characterized for operation from  $-40^{\circ}\text{C}$  to  $85^{\circ}\text{C}$ .

## TYPICAL APPLICATION DATA

The unique structure used on the I/O ports and the parity inputs of these devices deserves some special consideration (see Figure 1). Only the input structure is shown. The conventional 3-state output structure associated with each I/O port has been omitted to facilitate understanding.

FIGURE 1. INPUT STRUCTURE

The two inverters (G1 and G2) have a transmission gate (TG1) connected in a feedback loop around them. This transmission gate is connected in an unusual fashion, that is, with the gates of both transistors connected to the output of G1. Thus, with the output of G1 at either a high or a low level, one or the other of the transistors will be turned on allowing feedback of the output of G2 to the input of G1. The effect of TG1 is that the input level will be maintained at whatever level existed prior to the bus being disabled or the level currently existing on the bus will be reinforced.

To understand the operation of this input, assume that initially the input is at a low logic level. As the input voltage is raised, TG1 sinks current to attempt to maintain the low level. However, TG1 consists of small geometry transistors and appears resistive as current flows thus allowing the input voltage to rise toward the threshold voltage of G1. When the threshold voltage is reached, G1 changes state causing G2 to change state. G2 then attempts to maintain a high level on the input through TG1. A similar operation occurs when the input voltage is decreased toward the threshold voltage of G1. G2 sources current through TG1 until the threshold is reached.

This characteristic of the input stage has some implications for the input current levels. With the input held at either VCC or GND, there is no voltage across TG1 and negligible input current. However, as the input voltage is raised from GND or lowered from VCC, the input current rises as the voltage across TG1 increases. The input current continues to rise until it reaches a maximum just as the threshold voltage of G1 is reached.

This configuration provides for minimum power dissipation when the bus is inactive (all outputs on the bus in the high-impedance state) and minimum susceptibility to noise on the bus during this time. The increase in input current may go unnoticed as it only occurs during transitions on the bus. Care must be taken when measuring input currents (e.g., at incoming inspection) to ensure that the input voltage is set to the correct value.

The use of these devices for interfacing to 8-, 16-, 24-bit-wide memory arrays with parity is illustrated in Figures 2, 3 and 4.
